Plant Breeding Research

MAX-PLANCK-GESELLSCHAFT

How do populations adapt?

Hard sweep model of adaptation

Haplotype structure can be used to identify regions implicated in *hard sweeps*

But what if adaptive traits are highly polygenic?

When adaptation acts
mainly on variation
that is already
segregating in the
population...

selection results in a shift in the
distribution of the adaptive trait...

and shifts in the distributions of many
underlying genetic variants

Hard sweeps may not play a major role under a polygenic model

Polygenic selection results in small shifts in frequencies at many loci, most of which were present in the population when the selection pressure arose

How can we detect adaptation from standing genetic variation?

Population differentiation

Population 1

Population 2

These methods rely on the simple assumption that the two populations differ with respect to some selection pressure

... but can we do better?

Concordance between phenotypes and environment suggests adaptation

Julian Huxley coined the term *cline* to describe these patterns

In 1938, Huxley coined the term *cline* to describe 'a gradation in measurable characters'

He reviewed contemporary studies of phenotypic variation in populations and argued that this is an area that should receive greater attention

No. 3587, JULY 30, 1938

Clines: an Auxiliary Taxonomic Principle

By Dr. Julian Huxley, F.R.S., Zoological Society, Regent's Park, London

MODERN taxonomy, after a phase of 'splitting', adopted the integrating principle of geographical replacement, thus uniting numerous forms previously styled species as geographical races or sub-species of a polytypic species or *Formenkreis*¹. It seems desirable, however, to go still further in the direction of synthesis. The naming and description of subspecific forms, however necessary, is not sufficient. Further, if not supplemented by some other method, it has two actual disadvantages—it focuses undue attention on named forms as against those which remain unnamed, even when the degree of distinctness is only slightly less in the latter; it also conveys a false impression of uniformity within the named group, and thus tends to inhibit the study of intra-group regularities of variation.

Some special term seems desirable to direct attention to variation within groups, and I propose the word *cline*, meaning a gradation in measurable characters. This, being technical, seems preferable to such a term as character-gradient or phrases such as 'geographical progression of characters', used by W. F. Reiche in his recent book "Elimination und Selektion". (Naturally, when it can be shown that such characters are non-genetic in origin, they will be valueless for taxonomic purposes.) Prefixes can be used to denote clines of different types, for example, ecocline, genocline (gradient in genes), geocline (geographical cline), chronocline (paleontological trend), etc. The term could be extended if desired, for example, to ecocline for regular trends in individual development.

Clines may be of inter- or intra-group nature. Inter-group clines connect the mean values of the subspecies of a polytypic species (or of the species of a geographical subgenus or *Artenkreis*²). Numerous regularities of this sort are known, for example, the Rules of Bergmann, Gloger, Allen, etc. Rensch³ has recently summarized the subject. Good examples affecting colour or size are found in many birds represented in Britain (wrens, puffsins, spotted woodpeckers, bullfinches, tits, etc.). An illuminating case is that of the wrens inhabiting Fair Isle⁴. These are not sufficiently distinct to be given a separate subspecific name, but are intermediate in character as well as in position between *T. i. troglodytes* of the mainland and the Orkneys and *T. i. zelandicus* of the Shetlands. To subsume these facts by a cline is to direct attention to a regularity that is concealed if we restrict ourselves to specification by the naming of areal groups.

Intra-group clines concern continuous variation within a population. Relatively little work has as yet been done on this laborious subject, for example, tongue-length in bees⁵; pericardial of 'spectacled' forms in gulls⁶; fin-rays in fish⁷; pattern in lady-beetles⁸; vertebrae in fish⁹; temperature-resistance in *Drosophila*¹⁰, etc. Surrance¹¹, in a coastal subspecies of *Oncomosa* (*Peromyscus*), has shown that the adaptively cryptic colour of the pelage changes gradually as one passes inland from

white sand to dark soil. Still further inland there exists a distinct and much darker subspecies on very dark soil, which also shows a colour cline, though less pronounced. Where the two meet, there is a narrow zone about three miles wide where the mean colour changes very rapidly, and the variability is much higher. Off the coast, on an isolated island of white sand, lives a much paler subspecies. Here we have, first, an inter-group cline comprising three subspecies, and also intra-group ones within the two inland groups. These run in the same direction as the inter-group cline, but are much less steep. These two geographical clines are separated by a very steep genocline (genocline) at the inter-breeding zone.

In plants, ecological clines appear to be the commonest type. Gregor¹², in *Plantago maritima* has shown that each ecological habitat selects out a particular assemblage of genocline types, so that a regular ecocline will run from more to less saline surroundings. It is probable that similar ecoclines are to be found among land-snails (Rensch¹).

It is in no way intended that specification by clines should replace any of the current taxonomic methods. It would constitute a supplementary method which, it is suggested, would correct certain defects inherent in that of naming areal groups, notably in stressing continuity and regularity of variation as against more distinctness of groups. It is important to note that clines for different characters may run in different directions (shrikes¹³, fox-sparrows¹⁴, lincoln sparrows¹⁵, etc.).

It would seem certain that, once attention is concentrated on this subject, regularities of intra-group variation will be found to be common—the rule rather than the exception. The correlation of these with environmental factors will undoubtedly often not be easy; and where the environmental factors vary in a complex way, the mere detection of regular phenomena may be difficult, though not impossible¹⁶. However, if the study of such regularities is actively pursued, I would prophesy that we shall eventually gain a new picture of species. In many cases at least, the species will prove to consist of a population showing adaptive clines running in various directions: the continuous gradation will be broken up by various forms of isolation, which, by impeding interbreeding and the free flow of genes, will accentuate the mean adaptive differences between adjacent groups, as well as in some cases introducing non-adaptive differences¹⁷. The term *cline* is put forward as a step in this direction.

I have to make grateful acknowledgments to a number of systematists with whom I have discussed the subject, and who allow me to say that they believe that the use of the concept in taxonomy would be useful, notably Mr. M. A. C. Hinton, Mr. N. D. Riley and Mr. J. R. Norman of the British Museum (Natural History), Mr. J. S. L. Gilmour and Dr. W. B. Turrill of the Royal Botanic Gardens, Kew, Mr. B. W. Tucker of Oxford, the Rev. F. C. R. Jourdain, and

...if the study of such [intragroup] regularities is actively pursued, I would prophesy that we shall eventually gain a new picture of species. In many cases at least, the species will prove to consist of a population showing adaptive clines running in various directions: the continuous gradation will be broken up by various forms of isolation, which, by impeding interbreeding and the free flow of genes, will accentuate the mean adaptive differences between adjacent groups, as well as in some cases introducing nonadaptive differences. The term *cline* is put forward as a step in this direction.

The paper was really an argument for 'lumping' vs. 'splitting'

Can we use clinal patterns to identify adaptive *genetic loci*?

Can we use clinal patterns to identify adaptive *genetic loci*?

Candidate gene study to examine correlations in Energy metabolism genes compared to background

Population history confounds efforts to identify adaptive loci with environmental association analysis (**EAA**)

- False positives result when population history is correlated with the environment
- Controlling for population structure can help expose true signals

Solution: Model population structure when assessing evidence for correlation with the environment

Bayenv compares the strength of evidence for a model with an effect of environment to the null

Null model:

$$H_0: y = \overset{\text{intercept}}{\beta_0} + \underbrace{\mu}_{\substack{\text{Random} \\ \text{effect due to} \\ \text{population} \\ \text{history}}} + \overset{\text{random error}}{\varepsilon}$$

Population allele frequency

The null model contains a term for population history

Alternative model:

$$H_1: y = \beta_0 + \underbrace{\beta_1 x}_{\substack{\text{Environmental} \\ \text{effect}}} + \mu + \varepsilon$$

Bayenv uses the (predicted) variance/covariance matrix to control for population structure

Energy metabolism variants are associated with winter temperature

Hancock et al., PNAS 2010

Variants associated with metabolic syndrome traits overlap with subsistence

Is detection improved by using the environment?

Environmental
Correlations

versus

Haplotype
Homozygosity

and

Population
Differentiation

Approach:

1. Compiled sets of variants associated with two phenotypes that are hypothesized to be under spatially-varying selection
2. Compared environmental correlations to traditional methods

EAA improves power compared to traditional approaches

“Agnostic” Genome Scans

Environmental Genome Scans

Selection scan rank-based p-value:

Conclusions: Clinal patterns in humans

- Subtle shifts in allele frequencies across regions and loci were important for adaptation to climate and subsistence in humans
- Environmental association analysis (**EAA**) can identify variants that will be missed using hard sweep or simple differentiation (F_{ST}) to detect positive selection

A. thaliana examples

A. thaliana is a useful model for learning about adaptations to climate

from Van Norman and Benfey 2009, adapted from Matthieu Reymond

- *A. thaliana* occupies a large range with extensive environmental variation
- Since *Arabidopsis thaliana* is largely inbreeding, the same accession can be used for genotyping, phenotyping and for follow-up functional analyses
- Genetic, genomic and molecular biology resources are well-developed for *A. thaliana* and complementary work provides valuable information about biology

A. thaliana is a winter annual

Which loci underlie adaptation to climate in *Arabidopsis thaliana*?

Using data for $\approx 215,000$ SNPs from 948 accessions, I identified variation that is strongly correlated with 13 climate variables

Climate variables included in the analysis

41 climate variables
summarizing information
about:

- Temperature
- Precipitation
- PAR
- Humidity
- Season Lengths
- Aridity

Pruned the complete set to choose 13
representative variables that fit into several
general groups:

- Daylength
- Extremes in T and precipitation
- Seasonality of T and precipitation
- PAR
- Humidity
- Season lengths
- Aridity

Do the results represent true signatures of positive selection?

Are variants that are likely to have functional effects enriched in the tails of the climate correlation distributions?

Biological processes are enriched in the tails

photosynthesis
red light signaling pathway

Photosynthesis

indoleacetic acid biosynthetic process*
gynoecium development*
maintenance of root meristem identity*
positive gravitropism*
cellular response to water deprivation*
stomatal complex development
cotyledon development
cotyledon vascular tissue pattern formation*
phloem or xylem histogenesis

auxin-related processes

regulation of defense response
jasmonic acid mediated signaling pathway

defense

* significant with $p < 6.83 \times 10^{-5}$ with Bonferroni

NS SNPs are enriched among top climate associations

intergenic synonymous non-synonymous

* $p \leq 0.05$

There is variation in signals among variables tested

Variables related to water availability show the strongest signals

No NS enrichment using a method that doesn't account for relatedness among individuals

Wilcoxon rank sum test enrichment:

The climate correlation results predict relative fitness in a common environment

147 accessions

Planted in a common garden in France

Can we predict relative fitness in a particular climate using genome scan results?

SNPs from the extreme
tail of the climate
correlation distributions

For each SNP,
determine which
allele is likely to be
favored in the climate
of interest

$\text{Fitness} \sim \# \text{ favorable alleles}$

Ask whether the
number of "favorable"
alleles predicts fitness

Can we predict relative fitness in Lille, France?

SNPs from the extreme tail of the climate correlation distributions

- Selected all SNPs in the 0.01% tail for any of the 13 variables
- If found for multiple, took the variable with the most extreme signal
- Removed SNPs in linkage disequilibrium

285 SNPs

254 SNPs

108 SNPs

Can we predict relative fitness in Lille, France?

For each SNP,
determine which
allele is likely to be
favored in the Lille
climate

- Defined a “climate window” for Lille based on the distribution of climate for complete set of 948 accessions
- For each SNP, determined the “favored” allele by asking which allele was more common in the *Lille climate window*
- Calculated the the number of ‘favorable’ alleles for each of the 147 accessions with fitness data

The climate correlation results predict relative fitness in a common environment

The tails of the climate correlation distributions are enriched for locally adaptive variants

Likely functional loci are enriched in the tails of the climate correlation distributions

1. Reasonable GO categories
2. NS/S SNPs
3. Loci involved in local adaptation from a field fitness study

Evidence for local adaptation in *A. thaliana*

Evidence of climate adaptation in the '1001 Genomes' Project data

Complete genome sequence data (Illumina) from 1137 accessions collected across Eurasia and North America

Which phenotypes were important for adaptation to climate?

Which biological processes are over-represented among the strongest correlations with climate?

Biological processes enriched with precipitation-related variables

Precipitation in the driest month

- **Maintenance of root meristem identity**
- Indoleacetic acid biosynthetic process
- Mitochondrial electron transport,

Precipitation in the wettest month

- **Pyridine nucleotide biosynthesis**
- Base-excision repair
- **Root hair cell tip growth**
- **Stomatal complex morphogenesis**

**Enriched biological processes provide validation
and suggest novel hypotheses**

Precipitation variables have the strongest enrichment of signals

10 loci with false discovery rate < 5%

- tRNA/rRNA methyltransferase (NS)
- 2 CYP450s (NS)
- Phosphatidylserine decarboxylase 3 (NS)
- Ethylene Response Factor 1 (ERF1)
- Electron carrier, oxidation reduction
- Copia TE
- Calmodulin-binding
- Beta-glucosidase 37 (Mirosinase)
- Pectin-like super-lyase
- Mildew-resistance (ATMLO11)

Environmental association analysis is applicable to diverse species

‘Top-down’ and ‘Bottom-up’ approaches for identifying adaptive variation

Ross-Ibarra et al., 2007

Increasing number of genome-wide SNP datasets enable EAA in diverse species

Examples of additional applications of EAA approaches*
